CSc 422 — Parallel Programming Project

Programs due Tuesday, March 5 (by midnight) Reports due Tuesday, March 26 (in class)

In this project you will develop efficient parallel programs for a grid computation, conduct timing experiments to analyze the performance of your programs, and write a report describing your results and what you have learned. The project is worth 60 points. I will award up to 6 bonus points (10%) for outstanding projects and reports.

You may work with a classmate on this project, and I encourage you to do so. However, you may do this project on your own if you prefer. Be sure to read and understand the entire assignment before you begin programming. There are lots of details, and they all matter!

Your programs must be turned in electronically by midnight on March 5. You will be doing timing experiments the week after Spring break. I will set up a schedule for the use of Parallel; each group will get several hours of stand-alone testing time. Your reports are due the second Tuesday after Spring break.

Programs

The starting point for the project is the following four programs. You may write the programs in MPD or in C with the Pthreads library. Develop your programs on Lectura or at home, but run experiments on Parallel.

- 1. Sequential Jacobi iteration program
- 2. Parallel Jacobi iteration program
- 3. Sequential multigrid program
- 4. Parallel multigrid program

Jacobi iteration is described in Sections 11.1.2 and 11.1.3 of the text. An outline of a sequential program is given in Figure 11.2; an outline of a parallel program is given in Figure 11.3. You will need to convert these to MPD or C plus Pthreads and to fill in all the details.

Multigrid methods are described in Section 11.1.6, but I do not give actual code. It is up to you to figure out the details for the sequential program and then to parallelize that program.

Your task is to write *efficient* programs. See the discussion on pages 539-40 of the text for the kinds of programming "tricks" that help make programs fast.

Initialize the boundary points of the grids to 1.0 and the interior points to 0.0. This will make it easy for you to check the correctness of your programs and the quality of the results for different algorithms.

For the parallel programs, divide the grid into horizontal *strips* of rows of points. This includes all the grids in the multigrid programs. Use one worker process per strip. Each strip should contain about the same number of rows so as to balance the computational load. (The largest strip should contain at most one more row than the smallest strip.)

In the parallel programs, implement an efficient *dissemination* barrier and use it when you need barrier synchronization. Use counter variables and busy waiting, as described at the end of Section 3.4. *Make sure your barrier is correct!*

For the multigrid programs, use a four-level V cycle as illustrated in Figure 11.8. Use the restriction and interpolation operators described on pages 550-51 of the text. Use Jacobi iteration for the iterations on each level. Use exactly *four* iterations on each of the finer grids, and use the command-line argument numIters (see below) for the number of iterations on the coarsest (smallest) grid.

Input and Output

Your programs should have three command-line arguments in the following order:

meshSize — the mesh size of the finest (largest) grid
numIters — the number of iterations to use on the finest grid
numWorkers — the number of worker processes for the parallel programs

Assume that all grids are square. You may assume that meshSize is a multiple of 16 times the number of workers. (This simplifies restriction and interpolation in the multigrid programs.) You should check this in your main function and exit with an error message if this is not the case.

For the parallel Jacobi iteration program, the number of *interior* rows in the grid is meshSize-1, and the *total* number of rows counting the top and bottom boundaries is meshSize+1.

For the multigrid programs, meshSize-1 is the number of interior rows in the *finest* (largest) grid. The mesh sizes of the coarser (smaller) grids should thus be meshSize/2, meshSize/4, and meshSize/8. As illustrated in Figure 11.7, the physical boundaries of all grids are the same, but the mesh size varies, and hence the distance between points also varies. You may use separate grids for each mesh size or do restriction and interpolation in place, whichever you prefer. (I believe it is easier to do restriction and interpolation in place, and hence the grids stack up on top of each other.)

The output from your programs should be:

the command-line arguments the execution time, in seconds, for the computational part the maximum error in final values on the finest grid the final values on the finest grid

Write the first three items to standard output. Write the data values to file data.out. The final data values are mainly for your purposes when debugging the program. (You may wish to output additional values while developing your programs, such as subsets of the rows in various grids.)

To calculate the execution time of the computational part, read the clock *after* you have initialized all variables. You should initialize grids *in parallel* in the parallel programs. Hence, you should have a barrier at the end of initialization (see Figure 11.3), and you should read the clock right after this barrier.

Read the clock again after you have finished the iterations and the calculation of the maximum error, but *before* you write the output. Again, make sure there is a barrier before you read the clock the second time.

The maximum error in final values should be the maximum difference between the final values of points on the finest grid and 1.0. One does not normally know what the final values should be, of course, but the maximum error is more interesting than the value of epsilon described in Section 11.1.

Timing Experiments

Your second task (during or after Spring break) is to run a series of timing experiments. In particular, you are to execute your programs for the following combinations of command-line arguments:

program 1 for mesh sizes of 192 and 384 program 2 for mesh sizes of 192 and 384 and for 1-4 worker processes program 3 for mesh sizes of 192 and 384 (largest grid) program 4 for mesh sizes of 192 and 384 and for 1-4 worker processes

There are a total of 20 different timing tests.

For each *sequential* program and grid size, first figure out what the value of numIters should be so that the execution time of the program is about 30 seconds for that grid size. Then use the *same* value of numIters for the parallel versions of that sequential program. You will thus be using four different values for the numIters argument.

If you write your programs in MPD, use the age() function to calculate execution times. The return value from each call of age() is the time in *milliseconds* since the program began execution. Hence, you will need to divide the elapsed time by 1000 to convert it to seconds. Be sure to set the MPD_PARALLEL environment variable to the appropriate number of processors for each test. Do not set MPD_PARALLEL just once; change its value every time you change the number of processors you are using in a test.

If you write your programs in C and Pthreads, use the times function, as illustrated in the clock.c and matrix.mult.c programs I handed out in class. (You can view the man page by executing "man -s 2 times".) The return value from times is the number of "clock ticks" since some time in the past (when the OS was last booted). The value of CLK_TCK is 100, hence you will need to divide the elapsed time by 100 to convert it to seconds.

Compiler Optimization Experiments

Compilers such as gcc and mpd by default produce code that is correct but not terribly efficient. These compilers will produce much better code if you turn on optimizations. With mpd, this is done using the -0 flag. With gcc, you have three choices: -0, -02, and -03, where -03 is the highest level of optimization.

In addition to doing the basic timing tests described above, you are also to determine how much faster your programs are if you turn on compiler optimizations. In particular, compile your programs with -0 for mpd or with -03 for gcc. Then repeat some or all of the timing tests. You do not need to repeat all 20 timing tests, but you do need to repeat enough of them to be able to reach conclusions about how much improvement one can get by having the compiler optimize the code that it produces.

Important Point: If you use C and Pthreads, be sure to declare shared synchronization variables such as barrier flags as volatile variables. With the -O3 level of optimization, gcc tries to put frequently used variables in registers. This is fine for sequential programs, but it usually breaks parallel programs. In particular, if a barrier flag is put in a register, then a change to the flag made by one process will not be seen by any other process!

Reports

Once you have done the timing and other experiments, write a report to explain what you have done and what you have learned. Your report should be a few pages of text plus tables and figures. It should have five sections, as follows:

- Introduction. Give a brief introduction to your report and a brief overview of your results.
- *Programs.* Summarize how each program works, and describe in reasonable detail all the program-level optimizations you have implemented to make your programs fast.
- *Timing Experiments.* Present the results from the timing experiments. Use tables to present the raw data and graphs to show speedups and comparisons. You do not have to use a graph-drawing program; it is fine to draw graphs by hand if you wish. *Also explain your results.* What do the results show? Why?
- *Compiler Optimization Experiments.* Explain the experiments you conducted to measure the effect of turning on compiler optimizations and the results you observed.
- Conclusion. Briefly summarize what your report has shown, and describe what you have learned from this project.

Electronic Turnin and Reports

By midnight on March 5 use turnin to submit your programs. The assignment name is parallel. The programs should be named progl, prog2, prog3, and prog4. Also submit a Makefile that we can use to compile your programs. In particular, if we execute

make progl

your makefile should compile progl (sequential Jacobi iteration) and produce an executable file that resides in a.out. We should then be able to execute the program with the command-line arguments specified above. You might also wish to turn in a README file.

We expect you to have completed efficient, working versions of your four programs for the timing experiments by March 5. When you run the timing experiments, you may find that you made mistakes and hence need to modify your programs. Before you turn in your report on March 26, turn in final versions of your four programs and Makefile. Use the same assignment name. (We will make a backup copy of the turnin area on March 6, and we will look at the differences between the original and final versions of your programs.)

Your reports are due *in class* on March 26. Please append commented listings of the final versions of your four programs to your report. If you changed your programs, *your report should also explain what you changed and why*. You do not need to turn in the actual output from any of your tests, but you should have it available or readily be able to reproduce it. In short, your report should contain all the information someone else would need to reproduce your results.
